A 7-year-old girl presented to the emergency department of a specialist paediatric hospital following an injury to her right elbow. The injury had been sustained during an unwitnessed fall from furniture. On examination, the patient was noted to have significant swelling of the elbow and restricted range of motion. A neurovascular examination was normal. Routine radiographs revealed a displaced fracture of the medial humeral condyle and an anterior dislocation of the ipsilateral radial head (Figs 1 and 2).

The operative management of this patient involved initial closed reduction of the radial head which was confirmed on image intensification. Following this, a medial approach to the condylar fracture was undertaken. With care to protect the ulna nerve, the fracture was reduced and held with two Kirschener wires. Image intensification was once again used to confirm the reduction (Figs 3 and 4). The patient was then managed in a long arm cast for 6 weeks after which the wires were removed.

At the 10-week follow-up appointment, the patient demonstrated normal alignment of the limb and a full range of motion. At a 6-month review, the patient was asymptomatic and had a full range of movement.

Fractures about the elbow are extremely common in children. In an epidemiological review, Litchenberg found that fractures about the distal end of the forearm are the most common, and that fractures and dislocations about the elbow are the next in frequency. Despite the frequency of elbow fractures in children, fractures of the medial condyle are very uncommon and account for less then 2% of all elbow fractures. Two mechanisms of injury have been proposed for this injury. The first, as demonstrated in our case, occurs following a fall on the outstretched hand with the elbow extended, with subsequent avulsion of the medial condyle. The second, less common mechanism occurs following a fall onto the olecranon which is driven into the trochlea and fractures the medial condyle.

Treatment of medial condyle fracture is based on the classification system of Kilfoyle. In this system, a type I fracture is non-displaced, and the fracture line does not go into the articular surface. The fracture line in a type II fracture goes through the articular surface, but the fracture is essentially not displaced. A type III fracture is totally displaced and rotated. Type I fractures heal with simple immobilisation. Type II fractures should be stabilised with percutaneous pinning if the reduction is
anatomic; however, if adequacy of the reduction is in question, open reduction and fixation of the fracture with Kirschener wires should occur. Type III fractures, as occurred in our case, require open reduction and fixation.

Similarly isolated dislocation of the head of the radius is extremely rare. This type of injury is most frequently associated with fracture of the ulna, thus being a type of Monteggia fracture-dislocation. Other published reports have shown dislocation of the head of the radius to occur with supracondylar and t-intercondylar fractures of the distal humerus. Whatever the associated fracture, the importance of radial head reduction should be emphasised because failure of reduction affects the long-term outcome. In children the preferred treatment is closed manipulative reduction. If, however, adequacy of the reduction is in question, operative treatment is always indicated.

In our case we have combined the above treatment principles resulting in a full recovery. Initially closed manipulative reduction of the head of radius was successful. This was followed by open reduction and internal fixation of the type III medial condyle fracture. This treatment should provide consistent outcomes in children with this rare injury.
