Environmental and Water Studies, Department of Civil and Environmental Engineering, Stanford University, Stanford, California, USA,a and Southern California Coastal Water Research Project, Costa Mesa, California, USAb

Enterococcus species composition was determined each hour for 72 h at a polluted marine beach in Avalon, Santa Catalina Island, CA. Species composition during the day was significantly different from that at night, based on an analysis of similarity. Enterococcus faecium and E. faecalis were more prevalent at night than during the day, while E. hirae and other Enterococcus species were more prevalent during the day than the night. Enterococcus spp. containing a yellow pigment were more common during the day than the night, suggesting that the pigmented phenotype may offer a competitive advantage under sunlit conditions. A laboratory microcosm experiment established that the pigmented E. casseliflavus isolate and a pigmented E. faecalis isolate recovered from the field site decay slower than a nonpigmented E. faecalis isolate in a solar simulator in simulated, clear seawater. This further supports the idea that the yellow carotenoid pigment in Enterococcus provides protection under sunlit conditions. The findings are in accordance with previous work with other carotenoid-containing nonphotosynthetic and photosynthetic bacteria that suggests that the carotenoid is able to quench reactive oxygen species capable of causing photoinactivation and photostress. The results suggest that using enterococcal species composition as a microbial source tracking tool may be hindered by the differential environmental persistence of pigmented and nonpigmented enterococci.
MATERIALS AND METHODS
Field site. Avalon Beach is located on Santa Catalina Island in the Southern California Bight. Waterborne enterococci at the beach are thought to emanate mainly from leaking sewer lines (3). Other enterococcal sources at the beach include sands and sediment, urban runoff, and wild animals, including birds (3).

Water sampling. Water was collected every hour from 0400 h on 19 August to 0300 h on 22 August 2008 in 10 m north of the Pleasure Pier at Avalon Beach (33°20.9’N, 118°19.5’W). Samples were collected at ankle depth on an incoming wave in an ethanol-sterilized, triple-rinsed bucket and transferred to a 20-liter 10% hydrochloric acid-washed, triple-rinsed cube container. The water was stored in the dark in a cooler and was processed within 6 h of collection.

Irradiance and tidal predictions. Simple Model of the Atmospheric Radiative Transfer of Sunshine (SMARTS) (16) was used to estimate UVB intensity every hour of the study. “Day” was used to describe times when there was sunlight, and “night” was used when there was no sunlight. Tidal predictions relative to mean sea level were obtained from online tidal calculators for Avalon, Santa Catalina Island, CA (http://tbone.biolo .sc.edu/tide/). When the tide relative to mean sea level was greater than or equal to 0.8 m, it was deemed “high,” and all other tides were deemed “low.”

Enterococcal enumeration and species identification. Enterococci were enumerated using EPA Method 1600 (32). The method uses membrane filtration and membrane-Enterococcus indoxyl-beta-D-glucoside (mEI) agar. Ten milliliters and 100 ml of each sample were filtered to obtain a countable number of colonies. Enterococcus concentrations obtained with this method over the 72 h are reported elsewhere (5). Ten presumptive enterococcus colonies from each time point were picked from mEI medium for species identification and subcultured onto tryptic soy agar (TSA) agar with 5% sheep blood (Northeast Laboratory, Winslow, ME) (here referred to as blood agar plates [BAPs]). In some cases, less than 10 colonies were archived due to lack of colony availability. Of the 72 time points, 10 colonies were obtained at 66 time points, 6 colonies at 2 time points, 5 colonies at 3 time points, and 3 colonies at 1 time point. After 24 h of incubation at 35°C, BAPs were assessed for strain purity by confirming that colonies were morphologically identical. Pure strains were subcultured from BAPs onto TSA slants (Northeast Laboratory, Winslow, ME) and incubated at 35°C for 24 h. TSA slants were subsequently stored at 4°C until species identification could be performed.

Isolates selected for species identification were subcultured from TSA slants onto BAPs 24 h prior to species identification. All isolates were first tested using the Vitek microbial identification system (bioMérieux, St. Louis, MO). Isolates identified as Enterococcus species but at low discrimination (<80% confidence level) were further tested using API 20S (bio- Mérieux, St. Louis, MO), an alternate species identification system used for Gram-positive cocci. Identifications by Vitek that were nondiscriminatory (e.g., E. casseliflavus/E. gallinarum) were tested using supplemental biochemical analyses, including motility, pigment production, and fermentation of arabinose, sucrose, and mannitol as per Facklam and Collins (11) and Ferguson et al. (12). These methods for enterococcus species identification are well established and have been shown to provide good agreement (>90%) with species identifications obtained using partial 16S rRNA sequencing (23). The presence or absence of pigment was determined for each isolate. The tip of a sterile cotton-tipped swab was touched to the surface of a single colony grown on BPA and held under a lamp. Yellow colonies were characterized as pigmented, as described by Facklam and Collins (11).

Microcosm experiments. The photoinactivation of nonpigmented Enterococcus faecalis (ATCC 19433), pigmented Enterococcus casseliflavus (ATCC 25788), and a lightly pigmented environmental isolate from Avalon Beach (identified as Enterococcus faecalis using the species identification procedures described previously and here referred to as E. faecalis AB) was tested. Experiments were performed in simulated seawater at pH 8.1. Simulated seawater was prepared in deionized water containing all major anions and cations, including carbonates (9, 14), and filter sterilized prior to use. All salts used were reagent grade or better.

Enterococcus spp. were grown in tryptic soy broth (E. faecalis and E. faecalis AB) or brain heart infusion broth (E. casseliflavus) to stationary phase at 37°C, as measured via spectrophotometry at a single wavelength of 650 nm. The density of cells at stationary phase was approximately 10^9 CFU/ml. Cells were then harvested by centrifuging and washed in phosphate-buffered saline (PBS; pH 7.32) three times. Cells were then resuspended in PBS (referred to as “seed stock”).

Fifty milliliters of simulated seawater and 0.5 ml of Enterococcus seed stock were placed in 100-ml sterile beakers wrapped in black electrical tape. No exogenous sensitizers (e.g., humic acid) were added because previous research indicated that the seawater at Avalon Beach was quite clear with few sensitizers (5). Beakers were placed in a recirculating water bath to maintain their temperature at 15°C, the temperature of seawater in central California, in a solar simulator (AltaSun Test CPS+; Linsengericht-Altenhaßlau, Germany) equipped with a coated quartz filter and a UV glass filter to block the transmission of wavelengths below 290 nm to simulate natural sunlight (passing wavelength, 290 < λ < 800 nm) (26). The irradiance was set at 400 W/m^2. The resulting light spectrum was measured using a spectroradiometer (RPS 200 and 380; International Light, Peabody, MA) and compared favorably to the light spectrum at Avalon Beach at 0900 on 19 August 2008, as estimated using SMARTS. Stir bars in the beakers ensured that the solutions were well mixed throughout the experiment.

One-milliliter samples were withdrawn from the beakers every 15 to 30 min. Appropriate sampling time intervals were determined using data from pilot experiments. Dark controls were run; seeded simulated seawater was stored in the dark at 15°C, and samples were collected every 30 to 60 min.

Enterococcus colonies were enumerated in each sample by spread plating appropriate dilutions in duplicate on TSA for E. faecalis and E. faecalis AB and on brain heart infusion agar for E. casseliflavus. Agar plates were incubated at 37°C, and colonies were counted after 24 h.

Photoinactivation experiments were performed in duplicate for E. faecalis and in triplicate for E. faecalis AB and E. casseliflavus. Dark controls were performed in duplicate for E. faecalis and once for E. faecalis AB and E. casseliflavus. Data from all replicate experiments are presented and used without averaging in the determination of decay rates (see below).

Statistical methods. Species composition was compared between day and night, as well as high and low tides, using the PRIMER program, version 5 (PRIMER-E Ltd., Ivybridge, United Kingdom). Bray-Curtis similarity matrices were created from square-root-transformed standardized species composition data. Analysis of similarity (ANOSIM) was used to determine whether there were significant differences in species composition between samples collected during the day/night or high/low tides. Differences in the occurrence of specific enterococcal species, as well as pigment versus nonpigmented enterococci during day versus night, were assessed using χ^2 tests (IBM SPSS Statistics, version 19.0; Chicago, IL).

For the inactivation experiment, concentrations of Enterococcus at each time point were normalized by the initial concentrations at time zero (−10^9 CFU/ml for all experimental conditions), and the natural logarithm of the normalized concentration was plotted as a function of time and fluence. Inactivation rate constants were calculated assuming Chick’s law applied using linear least-squares regression on the portion of data where exponential decay was observed, following the approach taken by others (17, 27, 28). The decay rates (slopes of the lines) were compared for the three organisms using multiple linear regression (25) to determine if they were significantly different. When replicate experiments were run, data were not averaged prior to curve fitting.

RESULTS
Field observations. The 72-h time series of presumptive enterococci measured using mEI medium was previously published by Boehm et al. (5). The data showed a statistically significant diurnal
trend, with concentrations being lower during the day relative to the night, and subsequent modeling confirmed the influence of photoinactivation on their concentrations.

The species of a total of 690 presumptive enterococci (∼10 from each time point) were determined to be E. faecium, E. faecalis, E. gallinarum, E. hirae, E. casseliflavus, E. durans, Aerococcus viridans, other enterococci, and nonenterococci (Table 1). The most common species was E. faecalis (308/690, 45%). The second most common species was the nonenterococcus Aerococcus viridans (119/690, 17%). Two of the isolates could not be identified and were designated as such. Of the isolates whose species were determined (n = 688), 82% were confirmed to be members of the genus Enterococcus.

The time series of raw species composition relative to solar intensity and tide level is shown in Fig. 1. To simplify data display, less common organisms (those where n was ≤8) were grouped into categories of “other enterococci” and “other nonenterococci,” as specified in Table 1. A diurnal pattern in both presumptive and confirmed enterococcus species composition was observed. When all species identified at the 72 time points were considered, there was a significant difference in species composition between day and night samples (ANOSIM global R = 0.147, P = 0.002) but no difference in samples collected at high versus low tides (ANOSIM global R = −0.007, P = 0.54). Results were similar when only confirmed enterococcal species were considered; enterococcal species composition was significantly different in samples collected during the day versus the night (ANOSIM global R = 0.055, P = 0.02) but not different in samples collected during high versus low tide (ANOSIM global R = −0.002, P = 0.45).

Variation in the occurrence of specific enterococcal species or groups (Table 1) during day and night was examined using χ² tests and contingency tables. E. faecium and E. faecalis constituted a greater proportion of the confirmed enterococci isolated during the night versus the day (χ² test, P < 0.01 for both), while E. hirae and the other enterococci group (see Table 1 for definition) made up a greater proportion of the enterococci isolated during the day than the night (χ² test, P < 0.05 for both).

The presence of a yellow pigment was assessed for each isolate, and occurrence of pigmented species was compared between day and night. Of all 690 isolates examined, 151 were pigmented. The species of 42% of these were subsequently found to be A. viridans, and 20% were E. gallinarum, 13% E. hirae, 11% E. casseliflavus, 7% E. faecalis, 3% E. cecorum, and 1% E. faecium. Eighty-eight of the pigmented isolates were confirmed to be Enterococcus. The fraction of confirmed Enterococcus isolates displaying a pigmented phenotype at each time point is provided in Fig. 2. The proportion of pigmented Enterococcus isolates was higher during the day

*The simplified designations are those used in Fig. 1.
(24% of confirmed *Enterococcus* species) than the night (8% of confirmed *Enterococcus* species) ($\chi^2$ test, $P < 0.0001$). If we include all isolates, even nonenterococcal ones, a greater proportion of isolates were pigmented during the day (31% of isolates) than the night (12% of isolates) ($\chi^2$ tests, $P < 0.0001$).

**Photoinactivation experiment.** The photoinactivation of *E. faecalis*, *E. faecalis* AB, and *E. casseliflavus* in simulated seawater was compared using a solar simulator. When all three organisms were exposed to identical simulated sunlight, an initial period of limited inactivation (shouldering) when decline was similar to that observed in the dark controls was observed (Fig. 3). For the two *E. faecalis* strains, this lag period lasted 60 min; for the *E. casseliflavus* strain, the lag period lasted 120 min. Thereafter, exponential decay was observed for all three organisms. *E. faecalis*, *E. faecalis* AB, and *E. casseliflavus* had first-order decay rates (± standard deviation) of $-0.1 \pm 0.005$, $-0.08 \pm 0.006$, and $-0.06 \pm 0.007$ min$^{-1}$, respectively. These rates may also be expressed as a function of fluence ($27, 31$) as $-0.04 \pm 0.002$, $-0.03 \pm 0.002$, and $-0.02 \pm 0.003$ cm$^2$/J, respectively. Multiple linear regression indicated that the decay of the nonpigmented *E. faecalis* strains was significantly faster than the decay of the pigmented strains ($P < 0.05$ for all comparisons). There was limited decline of the microorganisms in the dark controls over the course of the experiments (Fig. 3).

**DISCUSSION**

A diurnal pattern in enterococcal species composition was observed in hourly samples collected for 72 h at a marine beach in Avalon, Santa Catalina Island, CA. Fecal enterococcal species *E. faecalis* and *E. faecium* made up a greater fraction of the confirmed *Enterococcus* species at night than the day, while *E. hirae* and the other enterococci group (includes *Enterococcus* spp., *E. casseliflavus*, *E. durans*, *E. cecorum*, and *E. mundtii*) made up a greater fraction of the confirmed *Enterococcus* species during the day than the night. Although tidal and diel cycles are synchronized over a short period of 3 days, the tide was not an important controller of species composition. While there are certainly other controllers of species composition, including but not limited to temporally variable and differential sources, differential transport, grazing, and interaction with sediment, the results suggest that sunlight exposure influences the composition of enterococcal species at Avalon Beach.

A closer examination of enterococcal phenotypes indicates that a greater fraction of enterococci was pigmented during the day than the night, suggesting that the presence or absence of pigments could be one of the driving forces behind the observed diurnal pattern in species composition. Previous work with *Staphylococcus aureus* (8) and photosynthetic bacterial (19) mutants indicates that yellow carotenoid pigments, like those present in pigmented *Enterococcus* spp., are capable of quenching reactive oxygen species and play important roles in protecting organisms from photostress and photooxidation. Our experiments in the solar simulator indicate that a pigmented *E. casseliflavus* strain and a pigmented *E. faecalis* strain isolated from Avalon Beach decay more slowly than a nonpigmented *E. faecalis* strain. There are
more differences between the tested organisms than just the presence or absence of a pigment. The nonpigmented and pigmented \textit{E. faecalis} strains were not confirmed to be isogenic, and the pigmented \textit{E. faecalis} strain was less pigmented than the \textit{E. casseliflavus} strain, based on a qualitative evaluation of color. Regardless, the laboratory results suggest that the carotenoid pigment in the environmental \textit{E. faecalis AB} and \textit{E. casseliflavus} isolates may be capable of providing protection against photoinactivation.

An initial shouldering in the decay curves of all three tested \textit{Enterococcus} spp. was observed. A shouldering effect during inactivation experiments has been observed by numerous researchers in experiments involving both viruses and bacteria and has been attributed to shielding of organisms from inactivation by other organisms or particles, the requirement that multiple hits are needed for inactivation, and a threshold effect where a cell can withstand a certain level of stress before death occurs (7, 27, 28, 31). In the present experiment, the shouldering effect lasted 1 h for the \textit{E. faecalis} strains and 2 h for the \textit{E. casseliflavus} strain. Additional work will need to be done to investigate the cause of the differential lag periods.

The laboratory study aids in the interpretation of the field results and suggests that the presence of pigments in enterococci affects the fate of these organisms in the environment. The field results are consistent with the following conceptual model. Exogenous or endogenous sources seed both pigmented and nonpigmented enterococci into seawater. Once the sun comes out, enterococci are inactivated due to either direct or indirect photoinactivation; however, the pigmented enterococci do not inactivate as quickly as the nonpigmented due to the protection provided by the carotenoid. The result is that during the day, pigmented enterococci have a competitive advantage over nonpigmented enterococci, and thus, their relative abundance may be higher.

These findings have implications for using enterococcus species identification for microbial source tracking. Environmental and nonhuman enterococcal species are more likely to have pigments than human enterococcal species (1, 24). Assuming that the differential fate of \textit{E. faecalis} and \textit{E. casseliflavus} strains observed in our microcosms is representative of the differential fate of nonpigmented and pigmented \textit{Enterococcus} strains in general, the combined field and microcosm results suggest that species composition in sunlight-exposed water may not reflect that of the enterococcal source. During the dark, however, the ratio of pigmented to nonpigmented enterococci in water may better reflect the ratio of these organisms in their sources.

A secondary finding of this study is that the mEI medium used for the selective cultivation of enterococci allows the growth of \textit{Aerococcus viridans} at Avalon Beach. Seventeen percent of the 690 screened presumptive enterococci were \textit{A. viridans}. This is consistent with a study by Moore et al. (22) that also identified the enterococcal species from Avalon Bay during a different time period. However, they found 37% of their presumptive isolates to be \textit{A. viridans}. The discrepancy in the percentages presented by Moore et al. and those presented herein might be explained by the fact that those authors sampled exclusively during sunlit hours. In the present study, 27% of isolates collected during sunlight hours were \textit{A. viridans}, while just 6% of those species identified from nighttime samples were \textit{A. viridans}. The daytime percentage is closer to that reported by Moore et al. Interestingly, 63 (33% of the 119 \textit{A. viridans} isolates) were pigmented, which might indicate that this organism has a competitive advantage for surviving in sunlit waters.

There are several limitations of this study that should be acknowledged. First, only 10 presumptive isolates per time point were included in the species analysis. It would have been preferable to include more. However, samples in the presented statistical analyses were aggregated (by time of day or tide), so that a large number of isolates (between 400 and 500) were used in exploring various hypotheses. The microcosm studies compared pigmented versus nonpigmented \textit{Enterococcus} photoinactivation and just begin to explore the potential advantage for \textit{Enterococcus} to express the carotenoid pigment. More work is warranted to fully understand the role of the pigment in \textit{Enterococcus} ecology. Additionally, we measured inactivation as loss of culturability; unculturable organisms may be dead (due to cell lysis, for example) but also may remain viable and potentially undergo photorepair. The dynamics of the viable but nonculturable population of enterococci deserves future attention. The results described here apply to clear waters; the presence of particles in water may shield bacteria from sunlight and modulate photoinactivation rates. Finally, Ho et al. (18) suggest that diurnal variation in enterococcus concentrations at Avalon may be due to anthropogenic currents generated by the arrival of ferries in the harbor. Although several lines of evidence presented herein suggest that sunlight plays a role in modulating enterococcal species composition, the potential for diurnal currents or mixing to affect species composition remains a possibility.
